Abstract

In this paper, we investigate the use of DC (Difference of Convex functions) models and algorithms in the solution of nonlinear optimization problems by trust-region methods. We consider DC local models for the quadratic model of the objective function used to compute the trust-region step, and apply a primal-dual subgradient method to the solution of the corresponding trust-region subproblems.

One is able to prove that the resulting scheme is globally convergent for first-order stationary points. The theory requires the use of exact second-order derivatives but, in turn, requires a minimum from the solution of the trust-region subproblems for problems where projecting onto the feasible region is computationally affordable. In fact, only one projection onto the feasible region is required in the computation of the trust-region step which seems in general less expensive than the calculation of the generalized Cauchy point.

The numerical efficiency and robustness of the proposed new scheme when applied to bound-constrained problems is measured by comparing its performance against some of the current state-of-the-art nonlinear programming solvers on a vast collection of test problems.

Keywords: trust-region methods, DC algorithm, global convergence, bound constraints

1 Introduction

Consider the constrained nonlinear programming problem

$$\min \ f(x) \quad \text{subject to} \quad x \in C, \tag{1}$$

where $C \subseteq \mathbb{R}^n$ is a nonempty closed convex set and $f : \mathbb{R}^n \to \mathbb{R}$ is a twice continuously differentiable function. We have in mind a constraint set C over which projections are computationally affordable (like a set defined by bounds on the variables or other simpler settings such as the one considered in [9]). However, the algorithms and theory proposed in this paper apply to any closed convex set C.

Trust-region methods are widely acknowledged to be among the most efficient and robust methods for solving nonlinear optimization problems (see [8, 27]). A trust-region step results from the approximate solution of the trust-region subproblem, where a quadratic model of f is minimized over a trust-region ball of pre-specified size, possibly intersected with the feasible region C in the constrained case. When constraints of the form $x \in C$ are of polyhedral type, they can be naturally added to the trust-region subproblem (which would then consist of a quadratic program if the norm used in the trust-region ball is the ℓ_∞ one). Most trust-region methods compute the trust-region step in a way that the decrease produced in the quadratic model is a fraction of what is obtained by the so-called generalized Cauchy point, computed by determining the gradient-projected path (see [8, Chapter 12]).

The purpose of this paper is to integrate the DC Algorithm (DCA) [19, 20, 21, 22] in a trust-region framework for the solution of problem (1). DCA is a primal-dual subgradient method designed for solving a general DC program, i.e., an optimization problem where one minimizes the difference of convex functions on the whole space. We apply DCA to the approximate solution of the trust-region subproblems, exploring specific DC decompositions of the quadratic models. The overall approach is shown to be globally convergent to first-order critical points (when the second-order information used in the quadratic model DC decompositions is exact). We will see that the theory requires only one DCA iteration to solve the trust-region subproblem, which amounts to only one projection onto the feasible region and seems in general less expensive than the computation of the generalized Cauchy point.

Our numerical experiments are focused entirely on the solution of bound-constrained problems. The numerical tests reported in this paper showed us that a few (cheap) DCA steps suffice to compute decently accurate trust-region steps, resulting in an efficient and reasonably robust algorithm. The minimization of a nonlinear function subject to bounds on the variables has been the subject of intense previous work, along many possible avenues. Major classes of algorithms for bound-constrained problems include the ones based on: active or ϵ-active set methods (see, e.g., [1, 12, 31] and more recently [17] for a short review on active set methods); trust-region methods (see, e.g., [6, 7, 13, 23, 25]); interior-point methods (see, e.g., [5, 10, 18]); line-search projected gradient methods (see, e.g., [2] and the references therein; see also [3, 26, 34] for a limited memory BFGS method); and filter type methods (see [30]). The approach proposed and analyzed in this paper belongs to the trust-region class but also shares the flavor of projected gradient methods.

We organize our contribution in the following way. In Section 2 we provide some background on the DC Algorithm. Our DC trust-region method is introduced and analyzed in Section 3. The two following sections are devoted to present our numerical findings. First we provide in Section 4 practical details of the implementation of the DC trust-region method, as well as information on how the numerical experiments were done and compared. The numerical results are then presented and commented on in Section 5. Some final conclusions are reported in Section 6.

2 DC programming, algorithm, and models

Let us start by recalling some basic notions from Convex Analysis and Nonsmooth Calculus which will be needed afterwards (see [4, 28, 29]). In the sequel, the space $\mathbb{R}^n$ is equipped with the Euclidean inner product $\langle \cdot, \cdot \rangle$. The closed ball with center $x \in \mathbb{R}^n$ and radius $\varepsilon > 0$ is denoted by $B(x, \varepsilon)$.

For a proper convex function $g : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$, the subdifferential $\partial g(z)$ of g at a point z in its effective domain ($\{z \in \mathbb{R}^n : g(z) < +\infty\}$) is defined by

$$\partial g(z) \ = \ \{w \in \mathbb{R}^n : \ \langle w, d \rangle \leq g(z+d) - g(z), \ \ \forall d \in \mathbb{R}^n\}$$

(by convention $\partial g(z) = \emptyset$ if z is not in the effective domain of g).

We denote by $\chi_C(x)$ the indicator function of C, that is, $\chi_C(x) = 0$ if $x \in C$, otherwise $\chi_C(x) = +\infty$. For a nonempty closed subset C of $\mathbb{R}^n$, the normal cone of C at $x \in C$ is denoted by $N(C, x)$ and defined by

$$N(C, x) \ = \ \partial \chi_C(x) \ = \ \{u \in \mathbb{R}^n : \ \langle u, y - x \rangle \leq 0, \ \ \forall y \in C\}.$$

The normal cone is the polar of the tangent cone.

Next, we briefly review the underlying principles of DC Programming and of the DC Algorithm. A DC program is of the form

$$\inf \{g(z) - h(z) : \ z \in \mathbb{R}^n\}, \tag{2}$$

where g and h are lower semicontinuous proper convex functions in $\mathbb{R}^n$. The dual of this DC program is defined as

$$\inf \{h^*(w) - g^*(w) : \ w \in \mathbb{R}^n\}, \tag{3}$$

where g^* is the conjugate function of g,

$$g^*(w) \ = \ \sup\{\langle z, w \rangle - g(z) : \ z \in \mathbb{R}^n\}.$$

The DC Algorithm (DCA) is based on local optimality and DC duality, and has been introduced by Pham Dinh Tao in 1986 and extensively developed by Le Thi Hoai An and Pham Dinh Tao since 1994 (see [19, 20, 21, 22], and the references therein), being successfully applied to a number of classes of problems, including large-scale instances. DCA constructs two sequences $\{z^l\}$ and $\{w^l\}$ (candidates for being primal and dual solutions, respectively) which are improved at each iteration (and thus the sequences $\{g(z^l) - h(w^l)\}$ and $\{h^*(w^l) - g^*(w^l)\}$ are decreasing), in an appropriate way such that their corresponding limit points z^∞ and w^∞ satisfy local optimality conditions.

Algorithm 2.1 (DC Algorithm (DCA))

Initialization Choose $z^0 \in \mathbb{R}^n$.

For $l = 0, 1, \ldots$

1. Compute $w^l \in \partial h(z^l)$.

2. Compute $z^{l+1} \in \partial g^*(w^l)$, i.e., z^{l+1} is a solution of the convex program

$$\min\{g(z) - \langle z, w^l\rangle : z \in \mathbb{R}^n\}.$$

If some stopping criterion is met, then stop, otherwise go to Step 1.

Output Return z^{l+1} and $g(z^{l+1}) - h(z^{l+1})$ as the best known approximate solution and objective function value, respectively.

The type of algorithms for solving problem (1) of interest to us in this paper are based on the iterative minimization of quadratic models on the intersection of C with a trust region, and for this purpose we want to use DC programming. Note that when the set C is defined by bounds on the variables and we choose the ℓ_∞-norm for the trust region, the resulting trust-region subproblems will consist of minimizing a quadratic function subject to box constraints.

Given $x \in \mathbb{R}^n$, we form a Taylor quadratic model of f around this point

$$m(x+p, x) \;=\; f(x) + \langle \nabla f(x), p\rangle + \frac{1}{2}\langle p, \nabla^2 f(x) p\rangle.$$

Note that when $\nabla^2 f$ is Lipschitz continuous with constant $\kappa > 0$ on $B(x, \Delta)$, one has

$$|f(x+p) - m(x+p, x)| \;\leq\; \tfrac{\kappa}{6}\Delta^3, \tag{4}$$

for all $p \in B(0, \Delta)$.

The DC decomposition of $m(x+p, x)$ of most interest to us is

$$m(x+p, x) \;=\; m_g(x+p, x) - m_h(x+p, x),$$

where

$$m_g(x+p, x) \;=\; \frac{\rho_x}{2}\|p\|^2 + \mathcal{X}_D(p) \quad \text{and} \quad m_h(x+p, x) \;=\; \frac{\rho_x}{2}\|p\|^2 - m(x+p, x),$$

$\rho_x = \|\nabla^2 m(x+p, x)\| = \|\nabla^2 f(x)\|$, and $D = (C - \{x\}) \cap B(0, \Delta)$ is the intersection of C (shifted by x) with the trust region $B(0, \Delta)$.

3 The DC trust-region method

At the iteration k, a step p_k is computed by approximately solving the trust-region subproblem

$$\min\; m(x_k + p, x_k) \quad \text{subject to} \quad p \in D_k = (C - \{x_k\}) \cap B(0, \Delta_k), \tag{5}$$

using the DCA (Algorithm 2.1) and the DC decomposition

$$m(x_k + p, x_k) \;=\; \left(\frac{\rho_{x_k}}{2}\|p\|^2 + \mathcal{X}_{D_k}(p)\right) - \left(\frac{\rho_{x_k}}{2}\|p\|^2 - m(x_k + p, x_k)\right),$$

with $\rho_{x_k} = \|\nabla^2 f(x_k)\| + \epsilon$, where ϵ is a small positive quantity added to guarantee that ρ_{x_k} stays uniformly bounded away from zero.

The following algorithm summarizes our trust-region method using DCA for the trust-region subproblem minimization. The notation $P_W(z)$ denotes the projection of z onto W, when well defined.

Algorithm 3.1 (DC trust-region algorithm)

`Step 0` ***(initialization):***
Choose an initial point $x_0 \in C$ and an initial trust-region radius $\Delta_0 > 0$. Select a positive integer l_0. Choose constants η_1, γ_1, $\gamma_2 \in (0,1)$. Start with $k = 0$ and set $p_{-1} = 0$.

`Step 1` ***(step calculation using DCA for subproblem):***
Obtain p_k, with $\|p_k\| \leq \Delta_k$, by using DCA to approximately solve the trust-region subproblem (5), as follows:

Set $p_k^0 = P_{D_k}(p_{k-1})$.

For $l = 0, 1, \ldots, l_0 - 1$

1. *Compute $q_k^l = \rho_{x_k} p_k^l - \nabla m(x_k + p_k^l, x_k)$.*
2. *Set $p_k^{l+1} = P_{D_k}(q_k^l / \rho_{x_k})$.*

Set $p_k = p_k^{l_0}$.

`Step 2` ***(acceptance of trial point):***
Compute $f(x_k + p_k)$ and define

$$\tau_k \;=\; \frac{f(x_k) - f(x_k + p_k)}{m(x_k, x_k) - m(x_k + p_k, x_k)}.$$

If $\tau_k \geq \eta_1$, then $x_{k+1} = x_k + p_k$. Otherwise define $x_{k+1} = x_k$.

`Step 3` ***(trust-region radius update):***
If $\tau_k \geq \eta_1$ then $\Delta_{k+1} \in [\Delta_k, +\infty)$, otherwise $\Delta_{k+1} \in [\gamma_1 \Delta_k, \gamma_2 \Delta_k]$.

Increment k by 1 and go to `Step 1`.

Note that the minimal effort per iteration in this algorithm (when $l_0 = 1$) amounts to one projection, and this seems to be less expensive than the computation of a generalized Cauchy point (see [8, Algorithm 12.2.2]) for trust-region methods when applied to general convex constrained problems.

Algorithm 3.1 (when $p_k^0 = 0$ and $l_0 = 1$) becomes closer to DCA (when this latter one is applied to a smooth problem of the form (1)), since we have $\nabla m(x_k, x_k) = \nabla f(x_k)$ and thus we are essentially using something closer to a global DC decomposition for the original problem (1) rather than for the trust-region subproblem (5). However note that in such a decomposition the choice for ρ_{x_k} would be local (as it is in our case), and thus not rendering a true global DC decomposition.

We are now in a position to show global convergence to first-order stationary point.

Theorem 3.1 *Let $\{x_k\}$ be a sequence generated by Algorithm 3.1 applied to a twice continuously differentiable function f for which $\nabla^2 f$ is Lipschitz continuous on C. Then the sequence $\{f(x_k)\}$ is decreasing and $\lim_{k\to+\infty} \|x_{k+1} - x_k\| = 0$. Moreover, every limit point x_∞ of the sequence $\{x_k\}$ is a first-order critical point of problem (1), that is, $0 \in \nabla f(x_\infty) + N(C, x_\infty)$, where $N(C, x_\infty)$ stands for the normal cone of the convex set C at the point x_∞.*

Proof. Consider first the convex quadratic function in $p \in \mathbb{R}^n$ given by $m_h(x_k + p, x_k) = \frac{\rho_{x_k}}{2}\|p\|^2 - m(x_k + p, x_k)$. Hence, for every k and $l = 0, 1, \ldots, l_0 - 1$, one has

$$\langle q_k^l, p_k^{l+1} - p_k^l \rangle \;\leq\; m_h(x_k + p_k^{l+1}, x_k) - m_h(x_k + p_k^l, x_k), \tag{6}$$

where $q_k^l = \nabla m_h(x_k + p_k^l, x_k) = \rho_{x_k} p_k^l - \nabla m(x_k + p_k^l, x_k)$. On the other hand, since $p_k^{l+1} \in P_{D_k}(q_k^l/\rho_{x_k})$,

$$\rho_{x_k}\langle q_k^l/\rho_{x_k} - p_k^{l+1}, p_k^l - p_k^{l+1}\rangle \;\leq\; 0,$$

which is equivalent to

$$\langle q_k^l, p_k^l - p_k^{l+1}\rangle \;\leq\; \frac{\rho_{x_k}}{2}\|p_k^l\|^2 - \frac{\rho_{x_k}}{2}\|p_k^{l+1}\|^2 - \frac{\rho_{x_k}}{2}\|p_k^l - p_k^{l+1}\|^2. \tag{7}$$

From inequalities (6) and (7), one then obtains

$$m(x_k + p_k^l, x_k) - m(x_k + p_k^{l+1}, x_k) \;\geq\; \frac{\rho_{x_k}}{2}\|p_k^l - p_k^{l+1}\|^2$$

and therefore

$$\begin{array}{rcl} m(x_k, x_k) - m(x_k + p_k, x_k) & = & \sum_{l=0}^{l_0-1}[m(x_k + p_k^l, x_k) - m(x_k + p_k^{l+1}, x_k)] \\ & \geq & \frac{\rho_{x_k}}{2}\sum_{l=0}^{l_0-1}\|p_k^l - p_k^{l+1}\|^2 \;\geq\; \frac{\rho_{x_k}}{2l_0}\|p_k\|^2. \end{array} \tag{8}$$

Now denote by κ the Lipschitz constant of $\nabla^2 f$ on C. By the definition of τ_k, one has

$$|\tau_k - 1| \;=\; \left|\frac{m(x_k + p_k, x_k) - f(x_k + p_k)}{m(x_k, x_k) - m(x_k + p_k, x_k)}\right| \;\leq\; \frac{(\kappa/6)\|p_k\|^3}{\rho_{x_k}\|p_k\|^2/2l_0} \;=\; \frac{\kappa l_0}{3\rho_{x_k}}\|p_k\|.$$

Thus, since $\rho_{x_k} \geq \epsilon$ and $\|p_k\| \leq \Delta_k$, if

$$\Delta_k \;\leq\; \frac{3(1-\eta_1)\epsilon}{\kappa l_0},$$

then the iteration is successful. One can conclude that there is an infinity of successful iterations. Moreover, from the trust-region update of the algorithm, one has that

$$\Delta_k \;\geq\; \Delta_{\min} \;=\; \frac{3(1-\eta_1)\epsilon\gamma_1}{\kappa l_0} \quad \text{for all } k.$$

Therefore, $\tau_k \geq \eta_1$ when k is sufficiently large, and ignoring the unsuccessful iterations where there is no displacement one obtains

$$f(x_k) - f(x_{k+1}) \;=\; \tau_k\,[m(x_k, x_k) - m(x_{k+1}, x_k)] \;\geq\; \frac{\rho_{x_k}\eta_1}{2l_0}\|x_k - x_{k+1}\|^2. \tag{9}$$

Consequently, $f(x_k)$ is a monotonically decreasing sequence. Since f is bounded from below, $f(x_k)$ converges. As a result one has that $\lim_{k\to+\infty}\|x_{k+1} - x_k\| = 0$.

Let x_∞ be a limit point of the sequence $\{x_k\}$, say, $\lim_{i\to+\infty} x_{k_i} = x_\infty$ for some subsequence $\{x_{k_i}\}$ of $\{x_k\}$. For all $i = 1, 2, \ldots$ there exists an index $j_i \geq 1$ such that

$$x_{k_i} \;=\; x_{k_i+1} \;=\; \cdots \;=\; x_{k_i+j_i-1} \;\neq\; x_{k_i+j_i}.$$

One knows from (9) that $\lim_{i\to+\infty} \|p^{l_0}_{k_i+j_i-1}\| = \|p_{k_i+j_i-1}\| = 0$, and by using this and taking limits in (8), we obtain $\lim_{i\to+\infty} \|p^1_{k_i+j_i-1}\| = 0$. Since

$$\begin{aligned} & x_{k_i+j_i-1} + p^1_{k_i+j_i-1} \\ & \in \; P_{C\cap B(x_{k_i+j_i-1},\Delta_{k_i+j_i-1})}\left(x_{k_i+j_i-1} - \nabla f(x_{k_i+j_i-1})/\rho_{x_{k_i+j_i-1}} - \nabla^2 f(x_{k_i})p^1_{k_i+j_i-1}/\rho_{x_{k_i}}\right), \end{aligned}$$

we have

$$\langle -\nabla f(x_{k_i})/\rho_{x_{k_i}} - \nabla^2 f(x_{k_i})p^1_{k_i+j_i-1}/\rho_{x_{k_i}} - p^1_{k_i+j_i-1}, x - x_{k_i} - p^1_{k_i+j_i-1}\rangle \;\leq\; 0$$

for all $x \in C \cap B(x_{k_i}, \Delta_{k_i+j_i-1})$. By taking limits and recalling that $\Delta_k \geq \Delta_{\min} > 0$ for all k, one obtains the desired conclusion $-\nabla f(x_\infty) \in N(C, x_\infty)$. □

Interestingly, it is possible to replace τ_k by

$$\tau_k^{new} \;=\; \frac{2l_0(f(x_k) - f(x_k + p_k))}{\rho_{x_k}\|p_k\|^2} \tag{10}$$

and obtain a similar result.

Theorem 3.2 *Let $\{x_k\}$ be a sequence generated by Algorithm 3.1, under the modification* (10)*, applied to a twice continuously differentiable function f for which $\nabla^2 f$ is Lipschitz continuous on C. Then the sequence $\{f(x_k)\}$ is decreasing and $\lim_{k\to+\infty}\|x_{k+1} - x_k\| = 0$. Moreover, every limit point x_∞ of the sequence $\{x_k\}$ is a first-order critical point of problem $(\mathcal{P})$, that is, $0 \in \nabla f(x_\infty) + N(C, x_\infty)$, where $N(C, x_\infty)$ stands for the normal cone of the convex set C at the point x_∞.*

Proof. From (8) one obtains that $\tau_k^{new} \geq \eta$ implies $\tau_k \geq \eta$. Thus, if an iteration is successful for Algorithm 3.1 so it is for the modified version of the algorithm. The rest of the proof is exactly as in the one of Theorem 3.1. □

The search direction p_k could have also been computed by solving approximately the trust-region subproblem (5) using the DCA (Algorithm 2.1) and the DC decomposition

$$m(x_k + p, x_k) \;=\; \left(m(x_k + p, x_k) + \frac{\rho_{x_k}}{2}\|p\|^2 + \mathcal{X}_{D_k}(p)\right) - \left(\frac{\rho_{x_k}}{2}\|p\|^2\right),$$

with $\rho_{x_k} = \max\{-\lambda_{\min}(\nabla^2 f(x_k)), 0\} + \epsilon$, where $\lambda_{\min}(\cdot)$ denotes the smallest eigenvalue of a matrix. We would have also obtained the same convergent result for this decomposition as the one described in Theorem 3.1. However, each internal iteration of DCA would have then required the solution of an auxiliary problem of the form

$$\min\; m(x_k + p, x_k) + \frac{\rho_{x_k}}{2}\|p\|^2 - \langle p, q^l_k\rangle \quad \text{subject to} \quad p \in D_k,$$

which would have been more expensive when compared to what happens in Algorithm 3.1.

4 Implementation issues, test problems, and profiles

4.1 Implementation issues

To provide an assessment of the proposed methodology we developed an implementation for Algorithm 3.1, called `TRDC` (Trust Region Difference of Convex). As already mentioned in the introduction, our implementation only addresses bound-constrained problems, i.e., problems of the form (1) where $C = \{x \in \mathbb{R}^n : \ell \leq x \leq u\}$, with $\ell \in (\mathbb{R} \cup \{-\infty\})^n$ and $u \in (\mathbb{R} \cup \{+\infty\})^n$. To make projections onto $(C - \{x_k\}) \cap B(0, \Delta_k)$ fast, see (5), we considered $B(0, \Delta_k)$ defined using the ℓ_∞-norm.

While Algorithm 3.1 requests a positive integer l_0 (the number of internal DCA iterations), performing more internal iterations than needed to solve the trust-region subproblem (5) will lead to inefficiency. Also, considering $\rho_{x_k} = \|\nabla^2 f(x_k)\| + \epsilon$ may also lead to a high number of DCA internal iterations. Therefore, we stop the internal DCA iterations as soon as possible and consider an adaptive strategy for updating ρ_{x_k}, making it also dependent on the DCA internal loop counter l. Thus, ρ_{x_k} will be hereafter denoted by $\rho^l_{x_k}$. We start with a smaller value $\rho^0_{x_k}$ (set to $2^{-6}\left(\|\nabla^2 f(x_k)\| + \epsilon\right)$ in our implementation), and multiply it by a factor of $\rho_{factor} = 2$ in each inner iteration l, whenever a decrease in the quadratic model objective function is not achieved and until $\|\nabla^2 f(x_k)\| + \epsilon$ is not reached. Since DCA computes a monotonous decreasing sequence of iterates for the quadratic model, we stop the approximate solution (5) before l_0 is achieved (in our implementation $l_0 = 300$ was considered) if a decrease in the quadratic model is not observed and $\rho^l_{x_k}$ has already reached its maximum value of $\|\nabla^2 f(x_k)\| + \epsilon$ (recall that theory guarantees a decrease in the DCA quadratic model at iteration l when $\rho^l_{x_k} = \|\nabla^2 f(x_k)\| + \epsilon$). We used $\epsilon = 0.1$ in our implementation.

Since problem (1) is considered now of the bound-constrained type, we stop the external iterations whenever the scaled projected gradient is small enough, i.e., when

$$\frac{\|p - P_{D_k}\left(p - \nabla m(x_k + p, x_k)\right)\|_2}{0.01 \max\left(100, \frac{\|\nabla m(x_k+p,x_k)\|_1}{n}\right)} \;\leq\; \epsilon_{tol}, \tag{11}$$

or when p is a very small search direction ($\|p\| < \epsilon_{tol}$, setting $\epsilon_{tol} = 10^{-8}$). A run of `TRDC` is stopped unsuccessfully if it exceeds a maximum number of external iterations ($maxiter$), a maximum of total internal DCA iterations ($maxiterDCA$), or a maximum of objective function evaluations ($maxfeval$), with $maxiterDCA = 10^7$, $maxfeval = 1000$, and $maxiter = 1000$.

To improve numerical performance, we considered instead a scaled objective function f^*, given by $f^*(x) = \zeta f(x)$, with

$$\zeta \;=\; \min\left(1, \frac{100}{\|\nabla f(x_0)\|}\right),$$

where x_0 is the projection onto the feasible region of the user provided initial guess (e.g., given by CUTEr [14]). The scaling parameter ζ is computed at the algorithm initialization and kept fixed for the remaining procedure. When x_0 is not provided, we compute a feasible initial guess in the following componentwise fashion: the middle value of the bounds when both are finite, the finite bound when one of the bounds is finite, or 0 whenever the variable is free.

A final implementation issue is related to the update of the trust-region radius Δ_k, described in `Step 3` of Algorithm 3.1. We provide the details of the updating scheme for Δ_k in the following algorithm.

Trust-region radius update

- If $\tau_k > \eta_3$,
  - then increase the trust-region radius by setting $\Delta_{k+1} = \min(\bar{\gamma}_3 \Delta_k, 1000)$,
  - otherwise, if $\tau_k < \eta_1$
    - then set $\Delta_{k+1} = \bar{\gamma}_1 \Delta_k$
    - otherwise if $\tau_k < \eta_2$,
      - then set $\Delta_{k+1} = \bar{\gamma}_2 \Delta_k$
      - otherwise set $\Delta_{k+1} = \Delta_k$.

By taking $0 < \eta_1 \leq \eta_2 \leq \eta_3 < 1$ and $0 < \bar{\gamma}_1 \leq \bar{\gamma}_2 < 1$, $\bar{\gamma}_3 \geq 1$, this scheme satisfies the conditions required in `Step 3` of Algorithm 3.1. In practice, we started with $\Delta_0 = 1$ and used $\eta_1 = 10^{-3}$, $\eta_2 = 0.25$, $\eta_3 = 0.75$, $\bar{\gamma}_1 = 0.5$, $\bar{\gamma}_2 = 0.5$, and $\bar{\gamma}_3 = 2$.

4.2 Test problems

In order to insure a proper comparison of the implemented solver with state-of-the-art optimization solvers, we decided to consider the CUTEr [14] test problems collection. From the complete test set there available, we selected all the unconstrained and bound-constrained problems, resulting in the 271 test problems reported in Table 1.

4.3 Profiles

Using a large number of test problems demands for an aggregated way to show the numerical results. For a better visualization and brevity in the presentation of the numerical results, we are providing performance profiles obtained by using the procedure described in [11]. We consider also the modification made in [32] for the case where the metric used for performance does not always return a strictly positive value, as required in the original performance profiles. The major advantage of performance profiles is that they can be presented in one figure, by plotting, for the different solvers, a cumulative distribution function $\upsilon(\pi)$ representing a performance ratio.

The performance ratio is defined by setting $r_{p,s} = \frac{t_{p,s}}{\min\{t_{p,z} : z \in \mathcal{S}\}}$, $p \in \mathcal{P}$, $s \in \mathcal{S}$, where $\mathcal{P}$ is the test set, $\mathcal{S}$ is the set of solvers, and $t_{p,s}$ is a measure of performance of the application of solver s on test problem p. Then, one defines $\upsilon_s(\pi) = \frac{1}{|\mathcal{P}|}\text{size}\{p \in \mathcal{P} : r_{p,s} \leq \pi\}$, where $|\mathcal{P}|$ is the number of test problems. The value of $\upsilon_s(1)$ is then the percentage of times that the solver s wins over the remaining ones (or ties the best solver). If we are only interested in determining which solver is the best (in the sense that wins the most), we compare the values of $\upsilon_s(1)$ for all the solvers. At the other end, $\upsilon_s(\pi)$ for large values of π indicates the percentage of problems solved successfully by solver s, and thus serves as a measure of robustness.

Clearly, when for a certain problem $p \in \mathcal{P}$ one has $\min\{t_{p,z} : z \in \mathcal{S}\} \leq 0$, the value $r_{p,s}$ becomes meaningless or undefined for all $s \in \mathcal{S}$. We considered two possibilities to overcome this problem in our numerical results. One is to simply exclude all problems where such a situation happens, reducing the number of test problems to be included and then using the original performance profiles [11]. The second one is to keep all problems and to choose a way to deal with problems where $t_{p,s} \leq 0$ happens for at least one solver s. We considered $r_{p,s} = t_{p,s} + 1 - \min\{t_{p,z} : z \in \mathcal{S}\}$ whenever $\min\{t_{p,z} : z \in \mathcal{S}\} < 0.0001$ to overcome the possibility of $r_{p,s}$ being meaningless or undefined (see [32] for further details).

Table 1: CUTEr test problems used in the numerical results.

5 Numerical results

Since our proposed method uses second order derivatives we decided to compare it against `TRON` [24, 25], `IPOPT` [33], and `Lancelot B` [15] (available under the GALAHAD library [16]), which represent well the state-of-the-art optimization solvers where second order derivatives are used. `TRON` was specially developed to address bound-constrained optimization problems, while `IPOPT` and `Lancelot B` can handle more general constrained optimization problems.

Since the computational effort taken per iteration of `TRON`, `IPOPT`, `Lancelot B`, and `TRDC` is substantial different, we chose to compare the overall CPU time taken by the solvers. `TRON` and `Lancelot B` require as a stopping criteria the norm of the projected gradient (the numerator in (11)) to be smaller than ϵ_{tol}, while `IPOPT` uses the maximum between a scaled norm of the gradient of the Lagrangian and the complementarity residual. Since all stopping criteria used by the considered solvers are similar, one can consider their successful exit flags as an indication of whether a problem has been solved (up to a requested accuracy).

The numerical experiments were made in an Intel(R) Core(TM) Duo CPU computer, running at 2.66GHz, under a Linux operating system, using recent versions for all the solvers (`TRON` version 1.2, `IPOPT` version 3.10.1, and GALAHAD version dated of February 2011). The same exact CUTEr collection (version date `CUTEr: Mon Jan 8 15:36:20 EST 2007`) was used by the four solvers, and for each problem the same CUTEr initial point was considered. For each problem, a maximum running time of 3600 seconds was imposed to all solvers (i.e., a failure is declared for a solver on a problem if it is unable to provide an answer in less than 3600 seconds). The considered CPU time corresponds to the CPU time taken by the solver (excluding the CUTEr setup time) measured in seconds with two decimal places. Due to this limitation in measuring the solver CPU time, one can easily obtain $t_{p,s} = 0$ for many 'easy' problems.

A first set of performance profiles is provided in Figures 1 and 2, where all the test problems were considered and then the performance profiles from [32] were used. For a matter of visibility around $\upsilon_s(1)$ and along $\upsilon_s(\pi)$ for large values of π, we considered two subfigures in each figure. These profiles were depicted trusting the exit flag produced by each solver in order to check if success was attained on solving a given problem. From these performance profiles one can conclude that the `TRDC` solver is competitive in both efficiency and robustness, when compared to the other solvers, specially for problems with less than 2000 variables.

A closer look at these numerical results reveals that for problems `FLETCBV3`, `FLETCHBV`, `INDEF`, `QRTQUAD`, `SCURLY10`, and `SCURLY20` all the solvers were unable to converge. These problems seem to have an unbounded objective function and therefore were removed in the next round of profiles. Additionally, we list, on Table 2, the problems where a solver reported an unsuccessful exitflag, but the final objective function value is close to the one reported by the other solvers. For these problems we will now consider the run to be successful and use the corresponding CPU time. We point out that `TRON` always reports a successful exit flag (equal to zero), i.e., the only unsuccessful cases are due to exceeding the 3600 seconds running time limit.

The new performance profiles for the restricted test set are depicted in Figures 3 and 4. The relative position of each solver is similar, but these new profiles reassure the robustness of the `TRDC` solver, as it was able to solve more than 90% of the problems. Such a robustness is further confirmed as for problems `DIXON3DQ`, `LOGHAIRY`, `PALMER6C`, `PALMER8E`, `PENALTY1`, and `SCOND1LS`, the `TRDC` solver reported a failure, but the norm of the scaled projected gradient (11) is close to zero (lower than 10^{-2}), indicating the proximity of the final obtained point to the problem solution.

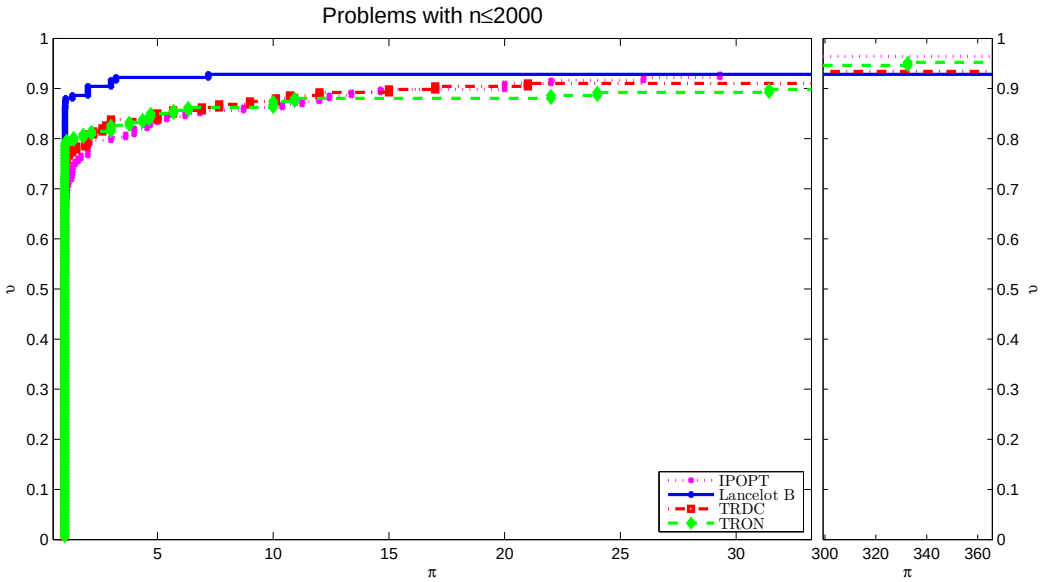

Figure 1: Performance profiles [32] for CPU time used by `TRON`, `IPOPT`, `Lancelot B`, and `TRDC`. Problems with $n \leq 2000$.

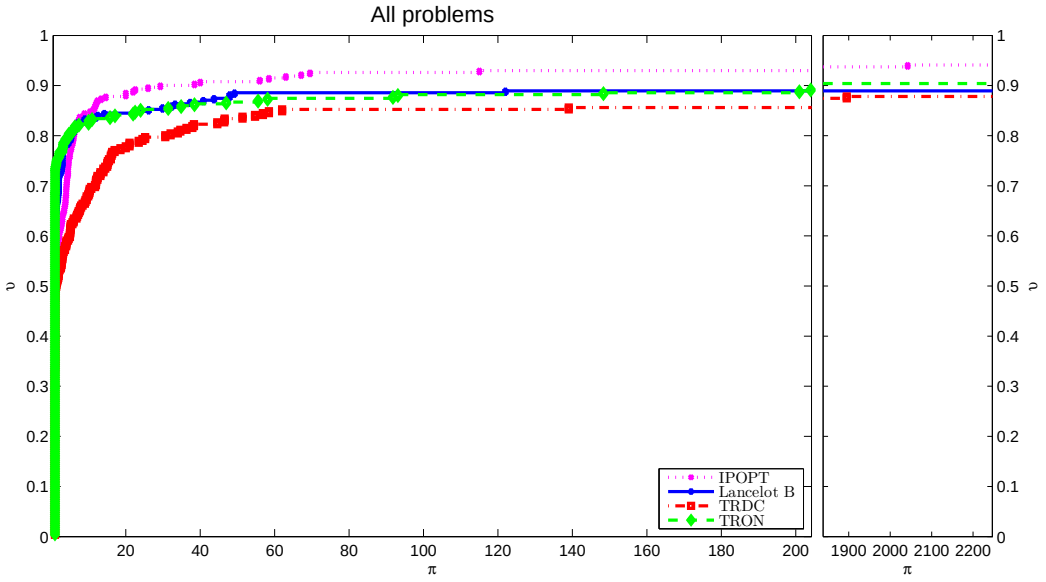

Figure 2: Performance profiles [32] for CPU time used by `TRON`, `IPOPT`, `Lancelot B`, and `TRDC`. All problems.

Table 2: Test problems considered as successfully solved despite an unsuccessful exit flag.

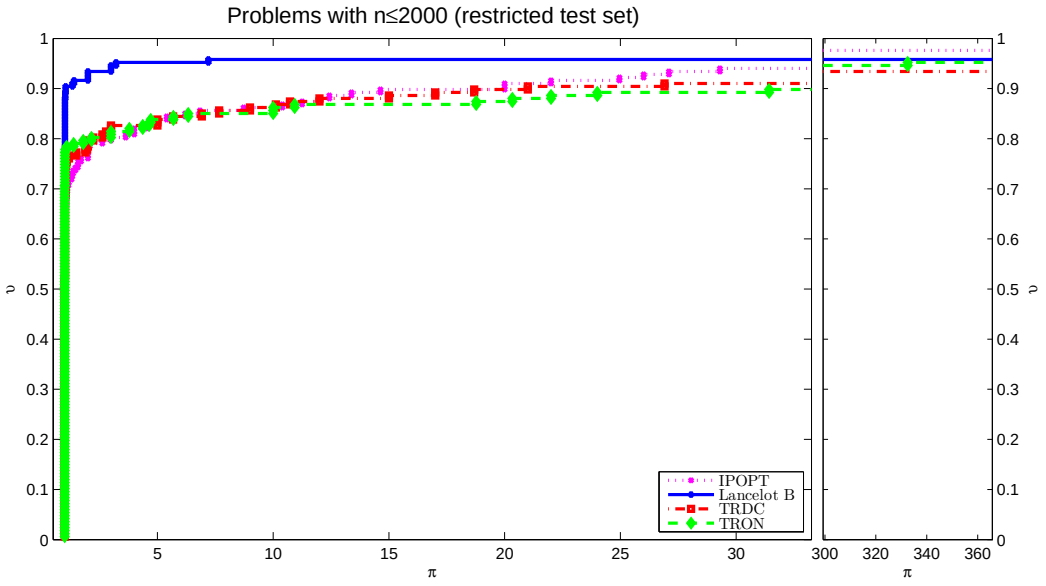

Figure 3: Performance profiles [32] for CPU time used by `IPOPT`, `Lancelot B`, and `TRDC`. Restricted test set, problems with $n \leq 2000$.

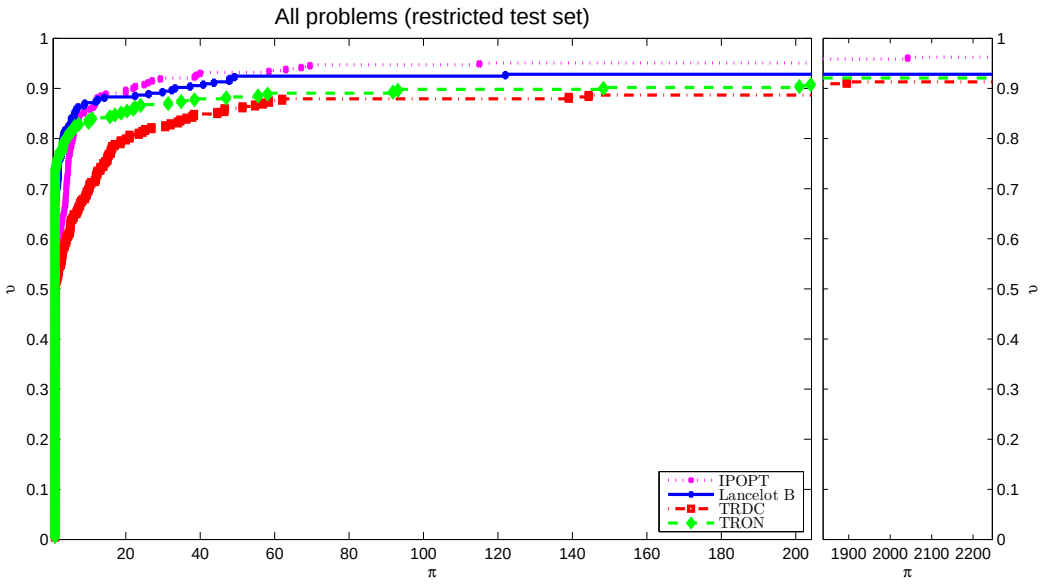

Figure 4: Performance profiles [32] for CPU time used by `IPOPT`, `Lancelot B`, and `TRDC`. All problems in the restricted test set.

We have also built other performance profiles, namely for the cases where the considered problems had dimensions $n \leq 10, 50, 100, 500, 1000, 3000, 5000$. We also plotted the performance profiles for each type of constraints available in the problems: unconstrained problems ($\ell = (-\infty)^n$ and $u = (+\infty)^n$), bound-constrained problems with at least one finite bound and one infinite bound, and bound-constrained problems with $\ell \in \mathbb{R}^n$ and $u \in \mathbb{R}^n$. Since we observed no major differences between these performance profiles and the ones reported before, we decided not to present them here for sake of brevity.

For a matter of completeness we also report our numerical findings using the original performance profiles [11]. In order to be able to plot these profiles we exclude from the test set all 'easy' problems for which $\min\{t_{p,z} : z \in \mathcal{S}\} = 0$ (i.e., all problems where at least one solver terminated using $t_{p,s} = 0$). This technique is the same as the one used in [17], where numerical results were restricted to problems with a running time of the fastest solver exceeding .01 seconds. These new performance profiles (for the restricted test set previously described) are presented in Figures 5 and 6. The number of problems is reduced from 167 to 39 (when $n \leq 2000$) and from 265 to 133 (all dimensions considered). While these new performance profiles are in accordance with the original ones in [11], the number of problems considered is considerably smaller and the best solvers are likely to be in disadvantage since problems where a solver attains $t_{p,s} = 0$ are removed from the analysis (disregardless of other solvers having or not $t_{p,s} \gg 0$).

From the depicted profiles for $n \leq 2000$, one can observe that `Lancelot B` is the most efficient solver, while `TRON` and `IPOPT` are the most robust. `TRDC` presents a similar performance in terms of efficiency and attains a robustness of about 85%. When all the problems in the restricted test set are considered we observe a slight disadvantage for the `TRDC` solver.

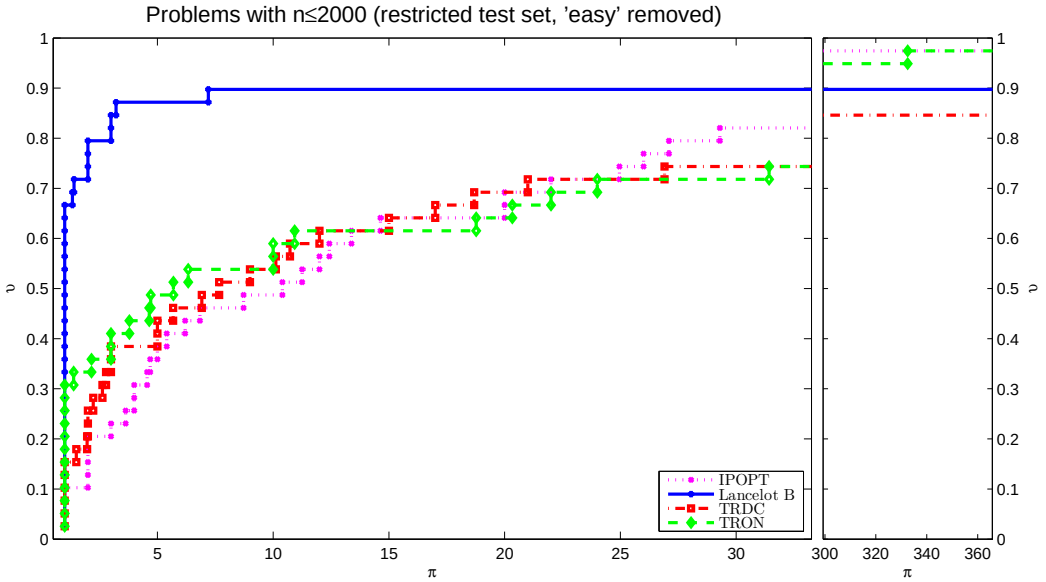

Figure 5: Performance profiles [11] for CPU time used by `IPOPT`, `Lancelot B`, and `TRDC`. Restricted test set, problems with $n \leq 2000$ except the 'easy' ones.

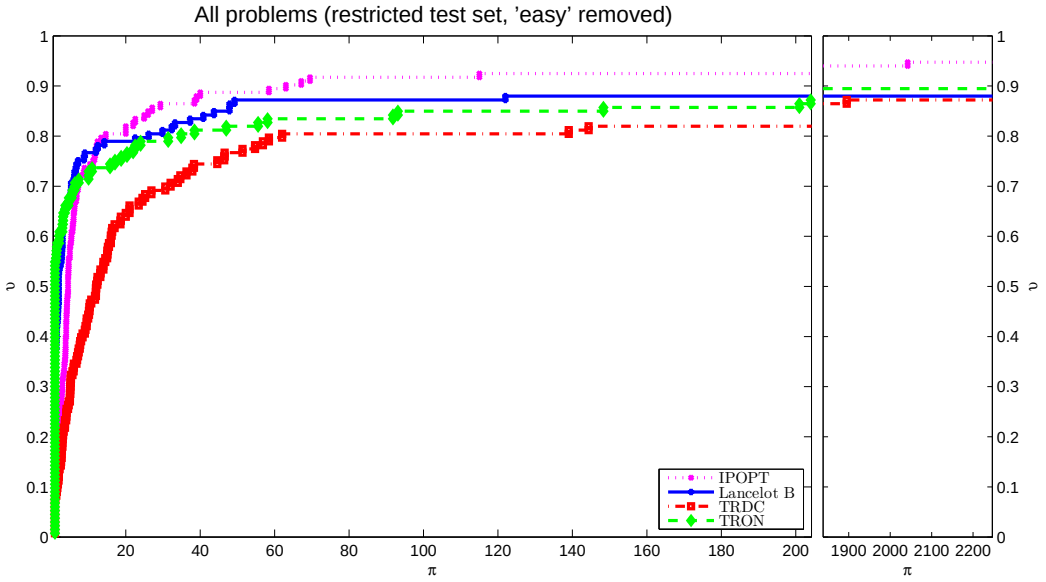

Figure 6: Performance profiles [11] for CPU time used by `IPOPT`, `Lancelot B`, and `TRDC`. All problems in the restricted test set, except the 'easy' ones.

6 Conclusions

A trust-region type method has been proposed, analyzed, and implemented, involving a new minimum requirement, from the solution of the trust-region subproblems, for achieving global convergence to first-order stationary points. Such a requirement, different from Cauchy or generalized Cauchy points, is related to the application of a first step of a primal-dual subgradient method (the DC algorithm), and it necessarily involves the knowledge of second-order derivatives, although it only requires one projection onto the feasible set. One is able to prove, in a relatively short and clean argument, that all limit points of the sequence of iterates are first-order critical. The numerical experiments reported show that the new approach is competitive with state-of-the-art solvers for problems with bounds on the variables.
